25 **Abstract**

26 Mayaro virus (MAYV) is an arthritis-inducing alphavirus circulating in the Americas, with

27 potential to rapidly emerge in new geographical regions and populated environments.

28 Intraparticle heterogeneity has typically limited atomic resolution structures of alphavirus

29 virions, while imposing icosahedral symmetry in data processing prevents

30 characterization of non-icosahedral features. Here, we report a near-atomic resolution

31 cryo-EM structure of the MAYV E1-E2-E3-CP subunit by addressing deviations from

32 icosahedral symmetry within each virus particle. We identified amino acid contacts at E1

33 protein interfaces forming the icosahedral lattice and investigated their effect on MAYV

34 growth through site-directed mutagenesis. Further, mutation of a short stretch of

35 conserved residues in E2 subdomain D, near an unidentified "pocket factor" including

36 E2Y358, significantly reduced MAYV growth and provides strong evidence that this

37 unknown factor influences assembly. Further, a symmetry-free reconstruction revealed

38 the MAYV virion is not strictly icosahedral, suggesting defects in global symmetry may

39 be a feature of the virus particle budding process. Our study provides insights into

40 alphavirus assembly and suggests a common path in the formation of spherical,

41 enveloped viruses, leading to particle imperfections.

Introduction

The *Alphavirus* genus (family *Togaviridae)*, contains arthropod-transmitted pathogens responsible for near-global epidemics in humans and livestock(Schmaljohn and McClain 2011; Strauss and Strauss 1994). Included in the genus are notable pathogens Chikungunya (CHIKV), Mayaro (MAYV) and Ross River virus (RRV), that account for millions of annual cases of debilitating, persistent polyarthritis across Africa, Asia, Australia, Europe and the Americas(Powers et al. 2001). These viruses continue to expand their geographic distribution, and the recent emergence of CHIKV in Asia and the Americas clearly demonstrates our inability to rapidly respond to and control their emergence(Kraemer et al. 2015; Tsetsarkin et al. 2007, 2009; Schuffenecker et al. 2006). MAYV primarily circulates within a sylvatic cycle in tropical forested regions of the Americas, though recent evidence of laboratory transmission by *Ae. aegypti, Ae. albopictus* and *Anopheline* vectors suggests potential adaptation to urban and peridomestic transmission(Acosta-Ampudia et al. 2018; Kantor et al. 2019; Torres et al. 2004; Mavian et al. 2017; Hotez and Murray 2017). MAYV exhibits significant cross-reactivity with other alphavirus species within the Semliki forest virus serogroup, and as a result cases are likely systematically misdiagnosed and underreported (Webb et al. 2019). Despite the increasing frequency of epidemics and expanding geographic range of many alphaviruses, there are no licensed vaccines or antiviral therapies for alphavirus infection.

The alphavirus genome consists of a single-stranded, ~11.5kb (+)RNA genome that encodes six structural and four non-structural proteins. The non-structural proteins (nsPs1-4) are essential for genome replication and immune evasion. The structural polypeptide (capsid(CP)-E3-E2-6K/TF-E1) is produced from a sub-genomic promoter and cleaved both co- and post-translationally. CP is first auto-proteolytically processed from the structural polypeptide and specifically interacts with the MAYV genomic RNA (gRNA) to form nucleocapsids (NCs). E1 protein has membrane fusion activity while E2 interacts with cell surface receptors and mediates cellular entry via clathrin-mediated endocytosis (Lescar et al. 2001; Smith et al. 1995; W. Zhang et al. 2005; Rong Zhang et al. 2018). E3 is essential for proper folding of p62 (the precursor to E2) and provides

80   stability of the E2-E1 heterodimer complex following cleavage by furin-like proteases

81   during passage through the trans-Golgi network(Carleton et al. 1997; Heidner, Knott,

82   and Johnston 1996; Mulvey and Brown 1995). 6K and TF are small lipophilic membrane

83   proteins with largely unknown function, though 6K has been implicated in membrane ion

84   permeability and virus budding(Melton et al. 2002; Firth et al. 2008; Lusa, Garoff, and

85   Liljeström 1991; Loewy et al. 1995).

86   Previous cryo-EM studies of several alphaviruses have revealed the organization of the

87   virus particle and individual E1-E2-(E3)-CP subunit(Paredes et al. 1993; Cheng et al.

88   1995; Rui Zhang et al. 2011). Particles are ~70 nm in diameter, with 80 protruding

89   spikes composed of trimerized E1-E2 heterodimer (20 icosahedral 3-fold and 60 quasi-

90   3-fold spikes) arranged in $T=4$ icosahedral symmetry. 240 copies of E1-E2 are

91   embedded in the lipid membrane, with a direct interaction between the cytosolic tail of

92   E2 and CP c-terminal binding-pocket(Taylor, Hanson, and Kielian 2007; Suomalainen,

93   Liljeström, and Garoff 1992). Alphavirus particles bud from the plasma membrane,

94   where E1-E2 complexes presented at the cell surface successively enwrap cytosolic

95   NCs enclosing the (+)ssRNA genome. The mechanism of membrane scission required

96   to release the nascent virion remains poorly understood, though it has been

97   demonstrated the process is independent of the host ESCRT system(Taylor, Hanson,

98   and Kielian 2007). While E2-CP interaction is essential to particle assembly, pre-

99   formation of cytosolic NCs through CP-CP contacts is not a strict prerequisite to particle

100   formation(Y. Zheng and Kielian 2015; Forsell et al. 2000).

101   Assembly of viral particles is a dynamic process, the endpoint of which depends greatly

102   on the kinetics and thermodynamics of subunit association as well as fluctuations to the

103   assembly conditions(Perlmutter and Hagan 2015). Production of virus particles with

104   significant defects, such as missing capsomers or local deviations from the global

105   symmetry, have been proposed to arise from independent assembly trajectories that

106   never reach the globally-symmetric conformation of lowest energy (Perlmutter and

107   Hagan 2015; Hagan and Chandler 2006). Rather than representing a population of

108   unproductive nascent particles, virions with deviations from global symmetry have been

109   proposed to possess a functional advantage due to the potential for more rapid

110   disassembly and release of viral genome(Wang, Mukhopadhyay, and Zlotnick 2018).

111   Traditional structural studies of spherical viruses by cryo-electron microscopy (cryo-EM)

112   have relied on high degrees of global symmetry in the data processing steps to greatly

113   increase averaging power and overcome the low signal of each radiation-sensitive virus

114   particle image. Potential defects in each virus particle image are either masked by the

115   symmetry applied in 3d-reconstruction, giving the appearance of a perfect particle, or

116   computationally discarded by only selecting the most homogenous, ordered particles for

117   the final structure.

118   Biochemical and 2D structural data indicate that purified CPs of Ross River virus do not

119   form complete icosahedral shells *in vitro* and incorporate shell defects (Wang et al.

120   2015). To assess whether alphavirus particles possess defects in the icosahedral

121   envelope and/or NC lattices, cryo-EM images of individual MAYV particles were first

122   examined in 2D for potential defects. Due to the prevalence of deviations from global

123   symmetry within each viral particle, an additional data processing protocol was

124   developed at the sub-particle level to identify and discard those distorted regions of

125   each virion image from the final average. This data processing increased the

126   resolvability of a well-ordered sub-particle region, without imposing icosahedral

127   symmetry in the reconstruction. Further, to better understand the deviations from global

128   icosahedral symmetry among MAYV particles, we determined an asymmetric 3d-

129   reconstruction of the virion. The resulting structure gives a novel insight into the

130   organization of the envelope glycoprotein (GP) and NC layers, with relevance to the

131   poorly understood mechanism of alphavirus budding.

132   By accounting for imperfections in the alphavirus particle lattice, we report a near-

133   atomic resolution cryo-EM structure of MAYV and the corresponding all-atom model,

134   and identify sites relevant to virus assembly at side-chain resolution. To validate the

135   importance of specific interfacial amino acid interactions, we perform structure-guided

136   mutagenesis experiments and assess the effects on MAYV replication. Based on these

137   results, we identify a novel site of lateral envelope interactions at the interface of

138   neighboring trimers that likely influences assembly of the MAYV icosahedron, and

139 validate a separate target for disruption of a lipophilic pocket with relevance to E1-E2

140 heterodimer assembly.

141

142 **Results**

143 **MAYV particles possess defects in the icosahedral lattice**

144 The cryo-EM structure of the MAYV virion was first solved to ~4.7Å by imposing

145 icosahedral symmetry, revealing a structural conservation typical of the alphavirus

146 family (Figure 1a-d). However, visual inspection of individual 2D images of MAYV

147 particles revealed significant heterogeneity, with virions apparently pleomorphic in

148 shape (Figure 2). Further inspection of the particle images revealed a few apparent

149 abnormalities: namely (1) missing capsomere units, (2) distorted and/or extended side

150 of particle and (3) multi-cored particles containing multiple, typically two, NCs

151 enwrapped in a lipid envelope decorated with envelope GPs.

152 To address the effect of incorrect assignment of asymmetric unit (ASU) orientations

153 throughout each virus particle image containing defects from global symmetry, an

154 additional data processing protocol was implemented. First, 60 masked subparticles,

155 corresponding to the 60 ASUs of the virus, were generated from each raw particle

156 image based on the rough icosahedral orientations. Each masked subparticle, centered

157 on a unique ASU and including additional padding density (Figure 1a), was then refined

158 against the MAYV penton reference with local c5 symmetry and 3d-orientation search

159 constraints. Each ASU subparticle was scored by phase residual agreement to

160 reference, regardless of the virus particle which it originated, and the highest-scoring

161 subset was retained for the final average. The additional protocol improved the map

162 resolution ~0.3Å beyond the icosahedrally-averaged map to 4.4Å, allowing for the first

163 slight separation of beta-strands in the E1-E2 ectodomain and observation of pitch in

164 the transmembrane (TM) helices (Figure EV 1a-b).

165 Non-crystallographic symmetry (NCS) was used to average the four quasi-equivalent

166 E1-E2-E3-CP subunits within the MAYV ASU, further improving the definition of the

167   peptide backbone and side chains (Figure EV 1b). The final NCS-averaged subunit

168   density map of the envelope was determined to 4.2Å resolution and C-terminal protease

169   domain of CP to 4.4Å resolution by gold-standard (0.143) FSC. Subsequent Q-score

170   analysis of the agreement between model and density suggests the E1-E2 ectodomain

171   structure meets the criteria of a map far better than 4.2Å resolution because many side

172   chain densities are apparent and rotamers can be properly modeled (Figure EV 2a-c)

173   (Pintilie et al. 2020a). Comparison of the MAYV atomic model with those of other

174   alphaviruses revealed high similarity between the protein domains (Figure EV 4). E1

175   ectodomain is divided into three domains: I, II (contains fusion loop) and III (lies parallel

176   to lipid envelope) (Figure 1c, Movie S1). E2 ectodomain is divided into four domains: A

177   (putative receptor binding function), B (putative receptor binding function, covering

178   fusion loop), C and a β-ribbon connector region (Figure 1c). Q-score analysis of the CP

179   supports the lower measured resolution in this region of the map, as the average

180   residue Q-score (Qresidue) of 0.48 is lower (corresponding to a lower resolution map)

181   than that of the E1 ectodomain (Qresidue 0.57) and E2 ectodomain (Qresidue 0.54)

182   (Figure EV 3a-c). Density corresponding to two N-linked GlcNac sugar moieties were

183   observed in the subunit density map, one at the surface-exposed residue E1 N141 and

184   the second at E2 N362 along the E1-E2 interface (Figure EV 5a-b). We also observe

185   density of cleaved E3 in our map in association with E2 beta-ribbon connector, in

186   agreement with its positioning in other alphavirus cryo-EM maps (Figure 1b).

187

MAYV particles have structurally ordered and disordered poles

189   To test the global symmetry of particles, an asymmetric reconstruction of MAYV was

190   determined by refining the orientation of each particle to one unique solution instead of

191   imposing icosahedral symmetry constraints. This symmetry-relaxation resulted in a

192   converged map of MAYV at ~9Å resolution. In contrast to the seemingly "perfect" MAYV

193   virion map calculated with icosahedral symmetry, the symmetry-free map contains

194   deviations from global symmetry. A highly structured side of the symmetry-free

195   reconstruction, which we termed this side the "leading" pole, is opposed by the most

196 disordered region on the other side of the virion, we refer to this as the "trailing" pole

197 (Figure 3a-d). The leading pole, approximately one-third of the particle, exhibits ordered

198 GPs, trans-envelope helices, and internal CPs of the nucleocapsid layer consistent with

199 the icosahedral reconstruction. Density becomes progressively weaker starting just

200 above the midpoint of the virion and ending at the disordered trailing pole. The density

201 of GPs, TM helices and NC at the trailing pole is largely missing, and appears distorted,

202 suggesting this region contains significant deviations from icosahedral symmetry.

203 After observing the polarity in icosahedral order in the asymmetric reconstruction, we

204 sought to better understand how the nucleocapsid was positioned relative to the GP

205 layer. We found that the NC density in the asymmetric reconstruction is positioned

206 equidistant from the GP layers at both the leading and trailing poles. Interestingly, the

207 NC region of most disorder at the trailing end correlates with the region of most

208 disordered GPs, lacking density of the TM helices and showing weak, distorted density

209 for the GP trimers. This suggests that NCs are not completely icosahedral in the mature

210 MAYV virion, and CP organization is likely modulated by the organization of the external

211 GP layer through direct contacts.

212

213 **Lateral envelope interactions on the virus surface**

214 80 trimers composed of E1-E2 heterodimers occupy 60 quasi-three-fold (q3) and 20

215 icosahedral three-fold (i3) positions of the MAYV *T=4* icosahedral lattice. These trimers

216 are arranged as 12 pentons with five-fold symmetry and 20 hexons with a two-fold

217 symmetry axis (Figure 4a). The lateral protein-protein interactions of the MAYV GPs can

218 be understood by observing the two distinct interfaces between neighboring trimers:

219 those formed by (1) i3-q3 trimers ("type I") and (2) q3-q3 trimers ("type II"). The type I

220 trimer interface is extensive (~990Å^2) and relatively flat, with five evenly-distributed

221 regions of inter-trimer contacts with quasi-2-fold symmetry (Figure 4b). In comparison,

222 the type II interface (~790Å^2) is situated at a greater angle, with three regions of

223 contacts positioned near the five-fold axis.

224   Side-chain interactions at Type II inter-trimer interfaces were identified with PyMol and

225   PDBePISA tool, and validated by assessing agreement between model and density

226   using a "Q-score" protocol (Figure EV 2b)(Pintilie et al. 2020b). Type II contacts were

227   investigated for influence on the icosahedral lattice due to the more limited overall

228   interface area and location near the five-fold axis. We generated MAYV-NLuc reporter

229   virus, with E2 N-terminus nanoluciferase fusion, to quantitatively measure viral titers of

230   WT and several MAYV point mutants and a deletion targeting the identified inter-trimer

231   contacts. MAYV-NLuc genomic RNAs (gRNAs) were transcribed and capped *in vitro*

232   and transfected into BHK cells via electroporation. Growth kinetics were assessed by

233   measuring luciferase activities in the culture supernatant every six hours for 48 hours

234   post-transfection (hpt) (Figure 4d).

235   Within the type II inter-trimer interface, a significant contact region is formed between

236   E1 domain I (E1DI) and E1DII of the neighboring trimer (Figure 4c). E1D151 main-chain

237   carbonyl (loop DIG_0) forms a H-bond with main-chain amino group of Y192 of

238   neighboring E1, while E1H152 can form a polar interaction with R206 of the neighboring

239   E1 molecule. Deletion construct E1ΔD151H152, made to abolish the inter-trimer H-bond

240   formed between peptide backbones, showed a significant 2-3 log reduction in growth

241   relative to WT at 18hpt and 2-log reduction at 48hpt. Nearby, E1K160 (loop DIH_0) forms

242   a H-bond with E1Y214 of the neighboring q3 trimer. Mutant E1K160A reduced virus

243   assembly relative to WT approximately 2-fold at measured time points. This difference

244   is clearly presented in linear scale (Figure 4d).

245   Additional type II contact regions near the five-fold axis were identified across E1DIII of

246   two E1 molecules from neighboring quasi-3-fold trimer. The first involves E1K382 that

247   forms multiple H-bonds with main-chain carbonyls of A20/R21 and Y1 of the

248   neighboring E1 (Figure 4c). Mutant K382A had no effect on virus assembly. The other

249   interaction, located directly at the five-fold axis, involves H-bonds between E1R349 and

250   main-chain carbonyls of V322 and I295. Mutant E1R349A showed 2-fold reduction in

251   growth at 24 hpt, after which virus production gradually approached that of WT.

252   Interestingly, in our structure I295 side chain atoms do not make inter-trimer contacts as

253 proposed for S295 in CHIKV and SFV, though a polar interaction does exist nearby

254 between E1T305 and E1S369 of the neighboring q3 trimer.

255

Unassigned factor in lipophilic pocket near viral membrane

257 Cryo-EM maps of alphavirus particles have consistently revealed density corresponding

258 to the major structural proteins E1-E2-CP, and in some cases the cleaved E3 (Rui

259 Zhang et al. 2011; Garoff, Simons, and Renkonen 1974; Basore et al. 2019). As first

260 noted in the map of Venezuelan equine encephalitis virus (VEEV), additional

261 unassigned density exists in a hydrophobic pocket formed by E2 subdomain D (subD)

262 and the top of E1 transmembrane helix closest to the outer leaflet of the lipid

263 envelope(Rui Zhang et al. 2011). Recently, this density has been termed a "pocket

264 factor" and its identity suggested to be the hydrophobic tail of a phospholipid(Chen et al.

265 2018). We observe the unassigned factor in our map of MAYV (Figure 5a) in the highly

266 lipophilic pocket (Figure 5c, Appendix Movie S1), where it runs roughly parallel to

267 E2subD and contacts residues E2H362, E2Y358 and E2P351. Interestingly, E2Y358 is

268 completely conserved in all mosquito-borne alphaviruses while E2H362 is highly

269 conserved (Figure 5b, Appendix Figure S1). In our map, the pocket factor is well-

270 resolved at density thresholds where E2 domain B is not, suggesting the factor is more

271 stably positioned than the flexible distal tip of E2. In addition to contacts between subD

272 and the lipophilic factor, we observe the H-bond between E2H348 and E1T403, first

273 noted in the structure of VEEV (residues E2H348, E1S403), that is proposed to stabilize

274 the orientation of E2 tail and E1 ectodomain lattice (Rui Zhang et al. 2011). Consistent

275 with the recent SINV cryo-EM structure, E2H352 does not form any E1-E2 contacts in

276 our map as previously suggested (Byrd and Kielian 2017), instead E2P351 forms a

277 contact with E1W407 (Figure 5c).

278 To assess the importance of highly conserved E2subD tyrosines to virus assembly

279 and/or replication, a triple substitution of Y357,Y358,Y359 with alanines was introduced

280 into our MAYV-NLuc reporter virus. In all cryo-EM structures with suitable resolution,

281 conserved residue E2Y358 (numbering differs) contacts the central region of pocket

282   factor (Figure 5c). Virus assembly, monitored as described previously, was significantly

283   reduced for the triple mutant E2_YYY357,358,359AAA by 2-3 log at measured time

284   points (Figure 5e). Loss of important contacts between E2subD and the pocket factor

285   could potentially destabilize the highly lipophilic pocket in its pre-fusion conformation,

286   leading to instability of the E1-E2 heterodimer assembly.

287

288   **Discussion**

289   The classical model of virus assembly requires each subunit to be arranged in

290   equivalent (*T=1*) or quasi-equivalent (*T>1*) chemical environments on the viral

291   capsid(Crick and Watson 1956; Caspar and Klug 1962). The association of individual

292   viral subunits into icosahedrons can be envisioned for ideal cases where kinetic or

293   thermodynamic traps are avoided, but the concurrent processes of subunit assembly

294   and budding of a planar membrane presents additional challenges(Hagan and Chandler

295   2006). Molecular simulation suggests steric clashes between GP trimers and extreme

296   negative membrane curvature of the late-stage budding "neck" can prevent

297   incorporation of GPs at the trailing end of the alphavirus particle (Lázaro,

298   Mukhopadhyay, and Hagan 2018a). Our visual inspection of MAYV particles and

299   focused classification of ASUs revealed significant defects to global icosahedral

300   symmetry within purified virus particles. While we cannot rule out mechanical damage

301   during virus purification or vitrification, we envision a cellular origin to these deviations.

302   Our observation of multi-cored particles, where GP trimers directly contact only one side

303   of the NCs, suggests an icosahedral GP layer completely wrapping around a NC is not

304   required for particle release. These unique particles support a model where virions

305   spontaneously achieve membrane scission or unknown host factors facilitate release

306   without completion of the icosahedron at the trailing end. It is also possible that these

307   multi-cored particles relieve kinetic stalls of the budding shells, proposed to occur at

308   mid- to late- stages of budding, through lateral GP self-interactions (Lázaro,

309   Mukhopadhyay, and Hagan 2018b).

310   In our asymmetric MAYV structure, we observed polarity in the resolvability of both

311   envelope GP trimers and NC capsomers from the ordered, leading pole to a more

312   disordered, trailing pole. To achieve this average, an icosahedral structure at one side is

313   opposed by either missing capsomers or ASUs in non-icosahedral positions.

314   Interestingly, asymmetric cryo-EM reconstructions of an immature and mature flavivirus

315   revealed similar polarity of structural order, with more extreme differences between the

316   poles and NC positioning in the immature particle containing GP trimers (Therkelsen et

317   al. 2018). Both alphaviruses and flaviviruses require GPs and NC for virus budding,

318   though the exact contribution of each component during assembly is not well

319   understood. The similarity between symmetry-free flavivirus and alphavirus

320   reconstructions can potentially indicate a shared mechanism of GP-driven assembly for

321   these icosahedral, enveloped virus families. The ordered, leading pole suggests lateral

322   GP trimer interactions can drive initial formation of the icosahedral lattice, while the

323   apparent deviations to icosahedral symmetry at the "trailing" end are expected due to

324   steric constraints at late stages of budding. In the alphavirus family, NCs are more

325   icosahedral in virions, presumably through direct interactions with symmetrically-

326   organized GPs. Our observations that CP density is lower resolution than the GP

327   ectodomain in the E1-E2-E3-CP subunit map, and that the NC does not show clear

328   icosahedral density at the "trailing" end of the asymmetric reconstruction, add evidence

329   that it is the GP layer that imparts icosahedral symmetry to the NC through direct E2-CP

330   interactions (Figure EV 3d). This agrees with previous studies of NCs assembled *in vitro*

331   or purified from infected cells that possess weak global symmetry prior to GP interaction

332   (Mukhopadhyay et al. 2002). We expect these deviations from global symmetry to be a

333   feature of GP-driven budding in other spherical, enveloped viruses, with potential

334   biological significance related to rate of budding and membrane scission, and the

335   potential for more rapid disassembly during entry in infected cells (Lázaro,

336   Mukhopadhyay, and Hagan 2018c).

337   Lateral E1 self-interactions guide assembly of the alphavirus icosahedral lattice, though

338   the essential molecular interfaces have yet to be defined and validated(Ekström,

339   Liljeström, and Garoff 1994). The alphavirus icosahedron is generally characterized by

340   loose interactions between GP trimers, where the spacing is proposed to facilitate a

341 transition of E1 fusion proteins from the pre-fusion to post-fusion conformation. In our

342 structure, we also observed a close packing of E1 molecules from neighboring trimers

343 at the 5-fold axis and identified nearby protein interfaces. Deletion of E1 residues

344 D151,H152 significantly reduced MAYV growth, presumably through disruption of an

345 interface between two quasi-3-fold spike trimers. Recently, a revertant mutation to the

346 assembly-impaired SFV E2 H348A/H352A double mutant was mapped to an inter-trimer

347 contact point in EI domain III at the five-fold axis, providing additional evidence this

348 region is an important determinant of alphavirus particle formation (Byrd and Kielian,

349 2019). Our cryo-EM structure can be used as a guide to perform mutagenesis

350 experiments to determine relative contributions of the interfacial residues around the

351 five-fold axis to the stability of the virus particle.

352 As previously described, the outer GP shell is linked to NC in the mature virus particle

353 by direct interaction between the Y-X-L motif of the E2 cytosolic tail and hydrophobic CP

354 binding pocket. The correct orientation of E2 endodomain presented at the cell surface

355 is critical for NC interaction, and it has been suggested interactions just above the viral

356 membrane between residues in E2 subD and E1 are important for correct positioning of

357 the CP binding site (Byrd and Kielian 2019). Within E2 subD we observe E1-E2

358 interactions between E2H348-E1T403 as well as E2P351-E1W407, comparable to

359 deposited heterodimer structures of other alphaviruses (Chen et al. 2018). First noted in

360 the cryo-EM structure of VEEV, unassigned density exists near two sequential,

361 completely conserved tyrosines (E2-Y359,Y360) in E2subD (corresponding to MAYV

362 E2-Y358,Y359). In our map we observed similar unassigned density near the outer

363 leaflet of the viral envelope, situated roughly parallel and contacting E2subD in a highly

364 lipophilic pocket above E1-E2 TM helices. Mutagenesis of conserved, sequential

365 tyrosines within E2subD (E2-Y357,Y358,Y359) to alanine resulted in a significant

366 decrease in MAYV production, presumably through disruption of a conserved contact

367 between Y358 and pocket factor. This suggests the pocket factor can modulate particle

368 assembly, presumably through stabilization of E2subD-E1 interactions and the E2 tail.

369 More work remains to evaluate the specific role of interactions with lipophilic factor and

370 nearby E1-E2 polar contacts, which can be essential for properly orienting both the E1

371 icosahedral lattice and cytosolic CP-binding motif.

372 In summary, deviations from global symmetry should be viewed as a general structural

373 property of alphavirus particles and warrants further investigation in other icosahedral,

374 enveloped virus particles. The polarity of structural order within particles gives rise to

375 interesting hypotheses about the assembly of icosahedral enveloped viruses driven by

376 membrane protein interactions and how it might differ from cytosolic assembly events.

377 From the near-atomic resolution structure of MAYV it was possible to identify and

378 validate targets for disruption of virus assembly. This includes targeting inter-trimer

379 interactions and the lipophilic pocket factor of the E1-E2 heterodimer. We anticipate this

380 structure will serve as a valuable resource for investigating MAYV particle assembly and

381 pathogenicity, identifying structural conservation in other alphavirus particles, and

382 designing future viral inhibitors.

383

384 **Materials and Methods**

385 **Virus purification**

386 Vero cells were prepared to 80–90% confluence and inoculated with MAYV at a

387 multiplicity of 0.1 plaque-forming units per cell. Infected cells were incubated at 37°C for

388 2 days or until cytopathic effects were observed. Cellular debris was removed from the

389 culture supernatant by centrifugation for 5–10 min at 1000–2000 g. Virus was

390 concentrated by precipitation with 7% polyethylene glycol 6000 and 2.3% NaCl at 4°C

391 for 12 h. Virus was then pelleted by centrifugation at 2500 g for 30 min and gently

392 resuspended in 2 ml TEN buffer (0.05 M Tris–HCl, pH 7.4, 0.1 M NaCl and 0.001 M

393 EDTA). The virus suspension was purified by centrifugation through a 20–70%

394 continuous sucrose/TEN gradient for 60 min at 35 000 g. The virus band was harvested

395 and centrifuged 5 × through Amicon 100 kDa filter (Ultra-4 Cat. No. UFC810024),

396 resuspending each time to maximum load volume with TEN. The purified virus was

397 harvested in the minimal remaining volume after final centrifugation.

398 **Cryo-EM sample preparation and data acquisition**

399　The preparation of MAYV particles was applied to Quantifoil copper EM grids with a

400　holey-carbon film and plunge frozen in liquid ethane using a FEI Vitrobot Mark IV

401　freezing apparatus. The frozen-hydrated MAYV grids were examined with a JEM

402　3200FSC microscope, operated at liquid-nitrogen temperature, and equipped with a

403　Gatan K2 Summit direct-electron detector. Images were collected in super-resolution

404　mode at 30,000x magnification and binned by 2 for processing of images at a pixel size

405　of 1.28Å. Each image exposure was for 5 seconds, with an electron dose rate of 7

406　electrons/pixel/second, resulting in a dose of 35 electrons on the specimen over a total

407　of 25 frames. In total, approximately 1100 images were collected, and 22,000 particle

408　images were selected for further processing. Micrographs were subjected to motion

409　correction and dose-weighting using Unblur software.

410　**Cryo-EM data processing**

411　An initial model from the 22,314 selected particles was first generated with the eman2

412　software package (Tang et al. 2007). The particles were then processed in jspr 3d-

413　reconstruction software, in which ctf parameters were estimated and particle centers

414　and orientations were iteratively refined with icosahedral symmetry to give a density

415　map at 4.7Å resolution after per-particle defocus and per-particle astigmatism

416　corrections (Guo and Jiang 2014). Subparticles were generated by expanding symmetry

417　from the icosahedral orientation of each particle image to all 60 ASU orientations,

418　followed by constrained refinement of subparticles using c5 symmetry. Sorting the

419　subparticles by phase residual agreement to a matching subvolume of the original

420　icosahedral map increased resolution to ~4.5Å. Non-crystallographic symmetry was

421　imposed to average the four subunits within each asymmetric unit. This was done by

422　loosely extracting volumes of each subunit in UCSF chimera and computing an all-vs-all

423　alignment using EMAN2 *e2spt_hac.py* program. This resulted in a final density map of

424　the subunit ectodomain at 4.2Å resolution and endodomain at 4.4Å resolution computed

425　by gold-standard fourier shell correlation. The figures were prepared using UCSF

426　Chimera (Pettersen et al. 2004) or UCSF Chimera X (Goddard et al. 2018).

427   An asymmetric reconstruction of MAYV using the 22,000 selected particles was

428   performed using RELION 3.0 (Fernandez-Leiro and Scheres, n.d.; Scheres 2012). Prior

429   to refinement, micrographs were further binned to a pixel size of 2Å, motion-corrected

430   using MotionCor2, and ctf parameters were estimated using CTFFIND4 (S. Q. Zheng et

431   al. 2017; Rohou and Grigorieff 2015). An icosahedrally-symmetric starting model of

432   MAYV was low-pass filtered to 60Å to blur the high resolution features. Orientations of

433   each particle were determined without imposing symmetry, with global angular search

434   value of 3.7° and local search angular increment of 0.9°. The orientation search

435   converged after 26 iterations, resulting in an asymmetric reconstruction at ~9Å

436   resolution using gold standard FSC criteria.

437   **Model building and refinement**

438   For proteins E1, E2, E3 and CP, homology models were first generated from the MAYV

439   primary sequence using Phyre protein structure prediction server(Kelley et al. 2018).

440   These models were fit into the respective density from the single MAYV protomer after

441   NCS averaging using UCSF Chimera and refined in real space using Phenix software

442   taking into account stereochemical and secondary structure restraints(Kelley et al.

443   2018; Pettersen et al. 2004). Further, an iterative process of manual editing of the

444   polypeptide backbone and rotamer placements using COOT and further Phenix real

445   space refinements was performed until the refinement statistics and visual fit of atoms

446   showed no clear improvement. To assess the resolvability of the map and the quality of

447   the model, Q-scores were calculated for each residue with the final model (Pintilie et al.

448   2020a). Refinement statistics of the structural model are listed in Appendix Table 1,

449   while plots of the Q-score values for each protein can be found in Figures EV 2 and 3.

450   **Reporter virus development**

451   The infectious clone of wild type MAYV CH strain was obtained from the World

452   Reference Center for Emerging Viruses and Arboviruses (WRCEVA) at the University of

453   Texas Medical Branch, Galveston, TX. The nanoluciferase gene was inserted between

454   E3 and E2 after the furin cleavage site within the MAYV genome using standard

455   overlapping PCR approach to generate a MAYV-NLuc construct. Site-directed

456 mutagenesis was performed by standard overlapping PCR approach. Molecular clones

457 of mutant viruses were confirmed by sanger sequencing prior to rescue.

458 **Assessing viral replication**

459 Viral genomic RNA from the wild type and mutant MAYV-NLuc clones were produced

460 by linearization with PacI then *in vitro* transcribed from an SP6 promoter using the

461 mMESSAGE mMACHINE kit (ThermoFisher Scientific). 10 ☐g of RNA was

462 electroporated into 1×10^7 BHK-21 cells which were grown in 15 ml DMEM media. 0.5 ml

463 of culture supernatants were collected every 6 hours and nanoluciferase activities

464 associated with released virus in the supernatants were measured using Nano-Glo

465 luciferase assay system (Promega).

466

467 **Acknowledgements**

474

475 **Author Contributions**

476 W.C., A.A., and S.W. supervised the study. A.A. prepared the sample for cryo-EM. J.J.

477 prepared virus mutant experiments. D.C. and J.K. performed cryo-EM sample

478 preparation. J.K. and D.C. collected cryo-EM data. D.C. and J.K. performed cryo-EM

479 image processing and structure determination; J.K. built and refined the model; D.C.,

480 J.K., A.A., J.J., S.W., and W.C. analyzed data. D.C. prepared figures. D.C. and W.C.

481 wrote the manuscript with input from all other authors.

Figure Legends

676 **Figure 1**. Cryo-EM structure of MAYV. (a) Radially-colored surface representation of

677 MAYV, with a central section to reveal interior of particle. Protein, lipid and nucleic acid

678 features are labeled in the central section surface view. Symmetry axes of virus

679 particles represented by white shapes (pentagon:5-fold, triangle:3-fold, ellipse:2-fold.

680 Masked region used for focused-refinement protocol of subparticles depicted as white

681 circles with dashed lines. Nucleocapsid density extracted and colored as cyan. (b) Side-

682 view representation of MAYV asymmetric unit (ASU) consisting of four E1(yellow)-

683 E2(red)-E3(pink)-CP(cyan) subunits arranged as a quasi-3-fold trimer and a single

684 subunit contributing to an icosahedral-3-fold trimer. (c) Density of E1-E2-CP subunit

685 after NCS-averaging of four quasi-equivalent subunits within one ASU, with fit backbone

686 model of each protein. Domains of E2 ectodomain (red circles) and E1 ectodomain

687 (yellow squares) labeled. (d) Representative density of E1/E2 ectodomain after focused-

688 refinement of subparticles ("best_ASU") and NCS averaging ("NCS_final").

689

690 **Figure 2**. Representative images of purified MAYV particles display significant

691 heterogeneity. Selected images are of particles belonging to each of four characteristic

692 virus morphologies ("icosahedral", "missing units", "distorted", and "multi-capsid"). Red

693 arrows represent locations of apparently missing or disrupted glycoprotein and/or

694 nucleocapsid layers, yellow arrows represent apparent axis of elliptical distortion, and

695 blue arrows highlight location of multiple capsids within one enveloped MAYV particle.

696 Scale bar: 50 nm.

697

698 **Figure 3**. Cryo-EM reconstructions of MAYV with and without icosahedral symmetry. (a)

699 Surface view of MAYV reconstruction with icosahedral symmetry imposed during data

700 processing with radial surface coloring. (b) Central section through the icosahedral

701 reconstruction reveals consistent structure throughout the virus particle. (c) Surface

702 view of asymmetric MAYV reconstruction without global symmetry imposed during

703 refinement, colored radially. Side view displays ordered icosahedral density while

704 bottom view displays weaker icosahedral features. Black line illustrates the axis of most

705 ordered density directly opposing the particle surface with least ordered density. (d)

706 Central section through the asymmetric reconstruction shows a clear polarity to order of

707 the glycoprotein ectodomains (yellow/red), lipid envelope/glycoprotein helices

708 (green/cyan) and nucleocapsid (dark blue/purple).

709

710 **Figure 4**. Lateral interactions between MAYV surface spikes. (a) Radially colored

711 surface representation of MAYV, with three neighboring surface trimers colored (E2-

712 purple, E1-cyan,yellow,orange). White triangle shows the position of 5-fold axis

713 (pentagon), 3-fold axes (triangles) and 2-fold axis (ellipse). (b) Molecular interactions

714 across E1 molecules of neighboring GP trimers displayed as grey spheres. Type I

715 interactions between quasi-3fold (yellow) and icosahedral-3fold trimers (cyan) and Type

716 II interaction between two quasi-3fold trimers (yellow and orange). The Pentagon

717 represents the position of the 5-fold axis. (c) Atomic interactions identified at the Type II

718 interfaces (I-IV), with zoned density around interacting residues. (d) Growth curves of

719 MAYV infectious reporter clone (WT and E1 mutants), measured by relative light units

720 (RLU) at time points up to 48hpi and displayed in linear and log scales.

721

722

723 **Figure 5**. Unassigned density in the cryo-EM structure of the MAYV E1/E2 heterodimer.

724 (a) E1-E2 heterodimer density (E1-yellow, E2-red) with unassigned "pocket factor"

725 density (sky blue). (b) E2 sequence alignment of multiple alphaviruses shows complete

726 conservation of E2Y358 and E2Y359 (MAYV numbering). Highly conserved residues

727 shown with red background and white font, somewhat conserved residues shown with

728 yellow background and red font. Sequence alignment performed using NPS and

729 ClustalW, formatted with ESPript. (CHIKV-Chikungunya virus, ONNV-O'nyong-nyong

730 virus, SFV-Semliki Forest virus, RRV-Ross River virus, EEEV-Eastern equine

731 encephalitis virus, VEEV-Venezuelan encephalitis virus, SINV-Sindbis virus). (c) Zoom-

732 in view of E2subD with zoned density around E2 residues forming contacts

733 (H362,Y358,P351) with the pocket factor. E1 residue W407 forms a E1-E2 contact with

734 P351. (d) Pocket factor and surrounding density as represented by molecular

735 lipophilicity potential, a three-dimensional representation of lipophilicity. Hydrophobic tail

736 of a phospholipid, as previously proposed (PDB:6IMM), is rigidly fit into the pocket factor

737 density and displayed (salmon). (e) Growth curves of MAYV infectious reporter clone

738 after transfection, including WT and E2 Y357A,Y358A,Y359A triple-alanine mutant as

739 measured by RLU.

740

741

742 **Expanded View Figure Legends**

743

744 **EV Figure 1.** Single particle cryo-EM data processing of MAYV virion. (a) Workflow

745 diagram of data processing, including gold-standard FSC curves of (I) subparticle

746 focused region and (II) after NCS averaging of four quasi-equivalent subunits. (b)

747 Representative density of E1/E2 ectodomain (top) and endodomain (bottom) after (I)

748 initial refinement using icosahedral symmetry, (II) focused sub-particle refinement, and

749 (III) focused sub-particle refinement + NCS averaging.

750

751 **EV Figure 2.** Model validation of the E1/E2 heterodimer ectodomains. (a) Transparent

752 density map with backbone model colored by residue Q-score for E2 (top) and E1

753 (bottom) ectodomains (b). Q-score for each amino acid residue in E2 (top) and E1

754 (bottom) model and 4.2Å map. Red line (0.41) represents expected Q value at 4Å

755 resolution based on correlation between Q-scores and map resolution. (c) Sample

756 density of E2 (top) including high- and low-scoring stretches of residue Q-scores and E1

757 (bottom), with residue (black) and Q-score (blue) labels.

758

759

760 **EV Figure 3.** Model validation of the MAYV endodomain. (a) Transparent density map

761 of endodomain with backbone model colored by residue Q-score. (b) Q-score for each

762 residue in capsid protein (CP) and 4.4Å map, red line (0.41) represents expected

763 residue Q-score in 4Å map. (c) Sample density of CP with model residues (black) and

764 Q-scores (blue) indicated. (d) Interaction interface between E2 (green) and CP (cyan).

765 Amino acid residues identified as forming E2-CP contacts are displayed with zoned

766 density. Table lists all residues identified in the forming E2-CP interface.

767

768

769 **EV Figure 4.** Comparison of alphavirus structures. Overlay of our atomic MAYV model

770 with other deposited alphavirus atomic models, aligned and colored by rmsd.

771

772

773 **EV Figure 5.** Glycosylation sites of MAYV. (a) Cryo-EM map of the MAYV trimer with

774 glycans shown (green). (b) E1/E2 heterodimer density with zoom-in views of both N-

775 linked glycans.

776

777

778 **Appendix Figure Legends**

779

780   **Appendix Figure 1.** Sequence alignment of alphavirus E1, E2, CP. Alignment

781   performed using NPS and ClustalW, formatted with ESPript.

782

783

784   **Appendix Movie 1.** Pocket factor location and interactions. Related to Figure 5.

785   Unmodeled density in the MAYV E1/E2/E3/CP subunit, initially colored as grey, sits in a

786   lipophilic pocket between E1 and E2. Residues of E1 and E2 that form continuous
787   density with this unassigned factor are displayed.

788

789   **Appendix Table S1.** Cryo-EM data collection, refinement and validation statistics.
